ABSTRACT

This report deals with differential equations and how they can be used to help the chemical engineer to size and optimize a CSTR reactor. The purpose of this article is to demonstrate the behavior of an elementary reaction where A forms B, in a first order reaction, to use the numerical methods of Euler and Runge Kutta to do so and to evaluate thermodynamic parameters of the reaction. These equations relate several characteristics of a fluid and for the type of specific reaction are tested to obtain the profile of Xa, Xb and γ, these being, dimensionless, that for Xa and Xb show how A is spent and B is produced and γ serves to relate the input temperature and at a certain point in the reactor. For the stationary solution, the bisection method was used to find the γ and then Xa and Xb. To solve the differential equations, the Euler and Runge-Kutta methods of the 4th order were used. From this the profiles were evaluated, and a great "sensitivity" was verified in the equations, since any change of parameters affected drastically in the iterations of the numerical methods. However, it was possible to find values for Xa, Xb and gamma that made chemical and mathematical sense for both a theoretical and a practical example (cyclopropane → propene). It was possible to evaluate the decay and ascent profiles of reagents and products using Excel as a tool, and the differential equations proposed in this study were successfully used.

Keywords: CSTR reactor modeling, chemical reaction, numerical methods, sizing, optimization.

INTRODUCTION

CSTR (continuous stirred tank reactor) reactors are used in chemical processes for mixing, reactions e crystallizations, has as main characteristic the continuous flow of reactants and products [1].

The Fig. 1 [3], represents a CSTR reactor, along with a cooling jacket.
The CSTR can be considered a basic chemical reactor. Its size can vary from a few liters to thousands of liters. They are used for various reactions involving the three states of matter: liquid, gas, or solid, when it uses catalysts [2].

The design of CSTR reactors is of extreme importance for the industry, since several types of reactions pass through it and, having ideal parameters that express a better efficiency, means less energy expenditure and greater production.

For this work numerical methods such as Euler and Runge-Kutta were used to solve differential equations. These equations relate parameters that take place on a chemical reaction, such as enthalpy, temperature, concentration and reaction rate. The use of numerical methods was needed because of the number of unknown variables. Transient state was considered for the mentioned methods.

In the Euler Method, which was introduced in a three-volume work, a sequence of approximations $y_1, y_2, y_3$...to the solution of a differential equation at $x_1, x_2, x_3$...is intended to eventually lead to the approximate and correct value [4].

Runge-Kutta is also an approximation but, being established way later, at the beginning of the 20th century, it results in much more accurate results [4].

The design of a CSTR reactor implies the evaluation of conditions that can be controlled and improved. When studying this type of subject, the engineer can avoid unnecessary losses and promote the maximum use of the raw material being used. The study of the mathematical equations that define certain behaviors within the CSTR reinforce the need to understand parameters such as temperature, pressure and reaction rate.

**Experimental**

Using as a starting point, a chemical reaction where A becomes B, and considering volume as a constant inside the reactor, the mass balance was made in Eqs. 1 and 2, to obtain the parameters of concentration inside the reactor with time. The energy balance was made, and it’s represented in Eq. 3, where the parameter of temperature with time is the one that should and will be considered for the numerical methods.

\[
\frac{V \cdot dCa}{dt} = q \cdot Ca e - q \cdot Ca - K \cdot Ca \cdot V \tag{1}
\]

\[
\frac{V \cdot dCb}{dt} = -q \cdot Cb + K \cdot Ca \cdot V \tag{2}
\]
\[ \rho . V . C_p . \frac{dT}{dt} = q . \rho . C_p . (T_e - T) + U . A . (T_c - T) + \dot{W} + \dot{R}_t + V \quad (3) \]

For these three, Board 1 was made to determine each parameter in the equations.

Due to the quality of parameters Pinto (2001), proposed a series of adimensionalizations for the equations. Eqs. 4 through 11, represent that.

\[
X_a = \frac{C_a}{C_{ae}} \quad (4)
\]

\[
X_b = \frac{C_b}{C_{ae}} \quad (5)
\]

\[
\theta = \frac{V}{q} \quad (6)
\]

\[
\theta_r = K_0 . \theta \quad (7)
\]

\[
\Delta Er = \frac{\Delta E}{R.T} \quad (8)
\]

\[
\beta = \frac{U . A}{q . \rho . C_p} \quad (9)
\]

\[
-\Delta h_r = \frac{C_{ae} . \Delta H_r}{\rho . C_p . T_e} \quad (10)
\]

\[
\gamma = \frac{T}{T_e} \quad (11)
\]

For these equations, it was possible to obtain three more, with the differential terms isolated for further application of the numerical methods. Eqs 12, 13 and 14 represent the differential terms Xa, Xb and \( \gamma \) respectively.
\[ \frac{dX_a}{dt} = 1 - X_a - \theta r \ast X_a \ast \exp \left( -\frac{\Delta E_r}{\gamma} \right) \] (12)

\[ \frac{dX_b}{dt} = -X_b + \theta r \ast \exp \left( -\frac{\Delta E_r}{\gamma} \right) \] (13)

\[ \frac{d\gamma}{d\tau} = (1 - \gamma) + U. \beta. (\gamma_c - \gamma) + \theta r. \Delta h r. X_a. \exp \left(-\frac{\Delta E_r}{\gamma} \right) \] (14)

To start the experiment, equation 14 had its differential term considered zero, so the reaction was stationary. After that, the bisection method was used to solve it and by having the value for gamma, the numerical values for Xa and Xb were obtained using the analytical solution with simple equations (no differential terms).

After that, Euler and Runge-Kutta were applied, and the values obtained were compared with the analytical solution to validate the use of Eqs. 12, 13 and 14. To demonstrate the results, tables and slopes were elaborated for this work, using Excel as main tool.

**RESULTS AND DISCUSSION**

As said previously, with Eq.14 having its differential terms equal to zero, bisection was used to solve it. Table 1, represents the data used for the terms ins the equation.

<table>
<thead>

</table>

So with a value for gamma, the analytical equations were utilized for Xa and Xb.
\[ X_a = \frac{1}{1 + \theta r \exp\left(-\frac{\Delta E_r}{\gamma}\right)} \]  

(15)

\[ X_b = \frac{\theta r \exp\left(-\frac{\Delta E_r}{\gamma}\right)}{1 + \theta r \exp\left(-\frac{\Delta E_r}{\gamma}\right)} \]  

(16)

With \( X_a = 0.111 \) and \( X_b = 0.888 \).

Then, differential equations were used, to check if they were valid or not and how sensitive each parameter was. At first the values from table 1 were applied in Eqs. 12, 13 and 14, but didn’t result on anything close to the analytical solution neither did it make sense mathematically. So, some subtle changes were made in those values, to check how it would respond. So, for \( \Delta E_r = 8.499 \) instead of 10, and \( \theta r = 52.909 \) instead of 50, the equation was valid and Table 3 represents the results.

Table 3 – Values for the Numerical Methods

</tr>
</tbody>
</table>

A step of 0.05 was used for the methods and 251 iterations were necessary for the result with error less than 0.001. Graphic 1 shows the slopes for Euler and Runge-Kutta using the information from Table 3.

Graphic 1 – Slopes for Numerical Methods

Xa e Xb using Euler e RK

Graphic 2 represents the slopes of gamma, which shows the variation of temperature inside the reactor at any given time.
The variation between methods, can be explained due to the sensibility of RK, being much bigger than Euler, and the curve for gamma goes much higher than the simpler method. The previous data is solved based on values coming straight from Pinto’s book, so to ensure the validity of the equations, the reaction of cyclopropane \( \rightarrow \) propene, was also studied. This reaction also has its volume as a constant, so the equations mentioned before can be used as well. Graphic 3 represents \( X_a, X_b \) and \( \gamma \).

Even though the slopes do not represent a big production of propene, they confirm that that differential equations used are valid and can be used for further works, taking into accounting their sensibility in changing of values for each parameter. To show that Graphic 4 represents what kind of changes can happen if we change (in this case increase), the parameter values for the equations. For a 10% increase, was evaluated how much gamma would vary from its equilibrium condition.
With that we can conclude that $\Delta E$ and $\beta$ are more sensitive to changes and influence temperature differential inside the reactor more than the others.

A little observation to be made, is that the excel tool writes the numbers with a comma, because it’s a Brazilian version, but those should be considered dots, for the International standards.

**CONCLUSION**

For the example using data from Pinto (2001), the differential equations showed to be valid, and for small changes made on the values of $\beta$, and $-\Delta E$, represented a big difference in the parameters $X_a$, $X_b$ and $\gamma$.

The same was seen in the reaction of obtention of propene. For this one, it was also concluded that gas reactions that have same stoichiometric number (for reactants and products) are also valid for the equations used in this work, since volume is also constant.

Runge-Kutta in comparison to Euler had a satisfactory behavior and it made possible to see the big jump in temperature inside the reactor, something that Euler didn’t show as much for the same data.
